Stressful life events and maltreatment in conversion (functional neurological) disorder: systematic review and meta-analysis of case-control studies

Summary
Background Stressful life events and maltreatment have traditionally been considered crucial in the development of conversion (functional neurological) disorder, but the evidence underpinning this association is not clear. We aimed to assess the association between stressors and functional neurological disorder.

Methods We systematically reviewed controlled studies reporting stressors occurring in childhood or adulthood, such as stressful life events and maltreatment (including sexual, physical abuse, and emotional neglect) and functional neurological disorder. We did a meta-analysis, with assessments of methodology, sources of bias, and sensitivity analyses.

Findings 34 case-control studies, with 1405 patients, were eligible. Studies were of moderate-to-low quality. The frequency of childhood and adulthood stressors was increased in cases compared with controls. Odds ratios (OR) were higher for emotional neglect in childhood (49% for cases vs 20% for controls; OR 5·6, 95% CI 2·4–13·1) compared with sexual abuse (24% vs 10%; 3·3, 2·2–4·8) or physical abuse (30% vs 12%; 3·9, 2·2–7·2). An association with stressful life events preceding onset (OR 2·8, 95% CI 1·4–6·0) was stronger in studies with better methods (interviews; 4·3, 1·4–13·2). Heterogeneity was significant between studies (P² 21·1–90·7%). 13 studies that specifically ascertained that the participants had not had either severe life events or any subtype of maltreatment all found a proportion of patients with functional neurological disorder reporting no stressor.

Interpretation Stressful life events and maltreatment are substantially more common in people with functional neurological disorder than in healthy controls and patient controls. Emotional neglect had a higher risk than traditionally emphasised sexual and physical abuse, but many cases report no stressors. This outcome supports changes to diagnostic criteria in DSM-5; stressors, although relevant to the cause in many patients, are not a core diagnostic feature. This result has implications for ICD-11.

Funding None.

Introduction Conversion (functional neurological symptom) disorder (DSM-5) refers to patients who have neurological symptoms in the absence of neurological disease, encompassing symptoms such as limb weakness, seizures, and movement disorders. Such disorders are one of the most common reasons for neurological referral (16% of new referrals) and are as disabling and distressing as neurological counterparts such as multiple sclerosis or epilepsy. Traditionally, the disorder has been diagnosed on both the absence of neurological disease and the “conflicts or other stressors [that] precede the initiation or exacerbation of the symptom or deficit.” However, the most recent edition of DSM-5 dropped the association with conflicts or other stressors as an explicit diagnostic criterion and emphasised the need to find positive clinical features such as Hoover’s sign in functional leg weakness or a sudden prolonged motionless unresponsive episode with eyes closed in dissociative (non-epileptic) seizure. This change has not been universally welcomed and whether ICD-11 will follow suit is uncertain.

Stressors, either recent life events, maltreatment around the time of symptom onset, or historical stressors, particularly childhood sexual abuse, have been considered key factors for the cause of functional neurological disorder since the time of Briquet’s 1859 Clinical and Therapeutic Treatise on Hysteria. In 1895, Breuer and Freud described the processes by which such psychological stress was converted into physical symptoms in their seminal Studies on Hysteria, giving the condition its name—conversion disorder—and a theory for cause that remains the bedrock of practice for most clinicians today. However, critics of the conversion hypothesis have commented that the empirical evidence to support the hypothesis is poor and that the dominance of the theory distorts clinician’s appreciation of the limitations of the available literature and inhibits the development of alternate or expanded models.

Previous reviews summarising studies of stressors, including maltreatment and stressful life events, in functional neurological disorder have either not been systematic, or have only reviewed non-epileptic seizures.
seizures\(^7\) or childhood sexual abuse.\(^7\) These reviews suggested an association of stressors and functional neurological disorder, but were of limited scope. When looking at more broad phenotypes, reviews of somatic symptom disorders have notionally included functional neurological disorder, but either did not identify much of the existing primary literature\(^8\) or were focused on functional somatic syndromes such as irritable bowel syndrome or chronic fatigue, which overlap with, but are different from, functional neurological disorder.\(^9\)

Technically, the study of maltreatment—used here as an umbrella term for sexual and physical abuse as well as emotional neglect—and stressful life events is challenging for many reasons. These challenges include patients’ willingness to disclose sensitive information (and possibly even awareness of it or of its potential relevance), recall bias, difficulty determining over what timeframe stressors are relevant, whether those that are present are relevant to cause, and the selection of appropriate controls. The use and selection of appropriate controls. The use and selection of appropriate controls.

Research in context

Evidence before this study

In the past decade, interest in conversion (functional neurological) disorders has upsurged. Largely dismissed during the latter part of the 20th century as a historical entity that was usually the product of misdiagnosis, high-quality evidence now shows that such disorders are common, disabling, and can be diagnosed accurately. The dominant view of cause had been that these symptoms arose as a consequence of the conversion of psychic distress into physical symptoms. With new research came new theories of cause; in particular, increasingly sophisticated models of mechanism based in neurosciences. These theories challenged the dominant view of psychological stressors being converted into physical symptoms. One view is that these new studies were complementary and simply explained the mechanism of conversion. Other clinicians and researchers took the stance that this mechanism was alternate and that conversion disorder could occur in the absence of identifiable exposure to stressors. DSM-5 took the latter view and was explicit that the presence of such stressors was no longer required, although paradoxically went for a compromise name: conversion (functional neurological symptoms) disorder. This opinion was not met with universal approval, and passionate debate still exists, but has often been shaped by individuals citing case examples from their own practice and less attention has been paid to the existing data from case-control studies. As a group of clinical researchers who have been involved in this debate but from opposing perspectives, we sought to systematically review the available literature. We searched PubMed and Science Direct for case-control studies in English from 1965 to Nov 4, 2016, with the search terms (“psychogenic” OR “conversion disorder” OR “non-epileptic”) AND (“abuse” OR “life event”) AND (“control” OR “controlled” OR “case-control”). This search was supplemented by reviewing the reference lists of eligible studies and previous reviews.

After removing duplicates and ineligible studies, we included 34 studies in our systematic review and meta-analysis.

Added value of this study

To our knowledge, this review provides the most comprehensive aggregation of the evidence from case-control studies since 1965. We covered the full phenotype of conversion (functional neurological) disorder, including both seizure disorders and motor or sensory disorders. We examined the frequency of stressful life events and of different types of maltreatment in childhood and adult life in patients with conversion (functional neurological) disorder and in both healthy controls and controls with neurological disease and psychiatric disorders. In addition to a qualitative review of individual studies, we quantitatively evaluated the association between stressors and functional neurological disorder, and did subgroup and sensitivity analyses to investigate sources of bias to understand the limitations to our data.

Implications of all the available evidence

Our results show that the rate of childhood and adult stressful life events and maltreatment, particularly emotional neglect, is increased in patients with conversion (functional neurological) disorder compared with controls. The association was stronger in cases of childhood onset and when we compared with healthy controls as opposed to disease controls. However, a proportion of cases report no stressors. We concluded that stressors are relevant to the cause and development of conversion (functional neurological) disorder and therefore a potential treatment target, but exposure to such stressors is not an essential diagnostic feature. Our findings support the changes to DSM-5 and have implications for ICD-11.
populations. We excluded physical injury, physiological events, or diseases as we have previously described their association to functional neurological disorder in previous systematic reviews and prospective studies.2,10,11

While setting our aims we were cognisant of two further arguments. First, we can only report measured life events and maltreatment. Different techniques can result in better or poorer reporting, but ultimately a distortion might exist between what was reported and what occurred. Second, thinking about stressful life events and maltreatment has been argued to be misleading and it is the patient's inner psychological state that matters, which clinicians and researchers say can only be uncovered by prolonged psychotherapy. This argument is exemplified by one of Freud's original cases of treated hysteria, Fräulein Elisabeth von R.7 Freud considered the stressor was having romantic feelings for her brother-in-law, which the patient always denied. She also disputed Freud's assertion that she recovered from her functional neurological disorder symptoms. The truth of the matter is unresolved. Our view is a pragmatic one: testing of subjective evaluation of emotions in a quantitative study would be very difficult and, more importantly, no empirical case-control data of this type for functional neurological disorder have been suitable for quantitative meta-analytic evaluation. Our study therefore evaluated the occurrence of reported events.

Methods

Search strategy and selection criteria
We searched the databases PubMed and Science Direct and the reference lists of eligible studies and reviews13,14 from 1965 to Nov 4, 2016. Search terms were (“psychogenic” OR “conversion disorder” OR “non-epileptic”) AND (“abuse” OR “life event”) AND (“control” OR “controlled” OR “conversion disorder” OR “non-epileptic”) and, more importantly, no empirical case-control data of this type for functional neurological disorder have been suitable for quantitative meta-analytic evaluation. Our study therefore evaluated the occurrence of reported events.

Data analysis

All primary studies were reviewed by one author (LL). A second author (JAP) checked the data and any discrepancies were arbitrated by two other authors (AC and JS). We collected data regarding (i) the setting of the samples; (ii) the nature of case and control groups; (iii) the sex and age of patients and controls; (iv) the instruments used to measure stressors; (v) the data on stressors; and (vi) the data from those studies that stated explicitly that the person had not had any maltreatment or stressful life event.

We assessed methodological quality of eligible studies using an adaptation of the Newcastle–Ottawa Quality Assessment Scale for case-control studies.15 The scale was adapted following the recommendations from Paras and colleagues.9 Individual quality items are listed in the appendix. The quality was assessed twice (by LL and JAP) and any disagreements were resolved by a further author (AC).

We calculated odds ratios (OR) with 95% CI for both dichotomous and continuous data. We used statistical approaches described by Borenstein and colleagues16 that allow data pooling. Furthermore, we used a proportion meta-analysis summary statistic for dichotomous data. Subgroup and sensitivity analyses were planned for the following grouping variables: study quality (median split of rating on quality scale, high vs low), type of control group (neurological disorder vs psychiatric disorder vs healthy control), age of population studied (children vs adults), type of symptom (non-epileptic seizures vs other symptoms), the time period where stressors occurred, and setting of the study (patients recruited in neurology vs psychiatry settings). We ran fixed-effect and random-effect models using StatsDirect (version 3.1.12). We quantified heterogeneity using a random-effect model, and publication bias using the Egger bias statistic and inspection of funnel plots. When more than one set of data from an individual study could be included in a summary meta-analysis, we used a hierarchy to choose one set to avoid duplication in the summary statistic: stressful life events (data from more recent timepoints first), childhood stressful life events, sexual abuse, physical abuse, emotional neglect, neurological control group, psychiatric control group, and healthy control group.

Finally, we calculated population attribution fractions (PAF) around the main estimates, taking data from a range of differing sources offering estimates based mainly on high-quality systematic reviews and meta-analyses of population prevalence.19–23 PAF is a measure of the contribution of a risk factor to a disease or a death at a population rather than individual level. It is the proportional reduction in population disease or mortality that would occur if exposure to a risk factor were reduced to an alternative ideal exposure scenario (eg, no tobacco use). PAF gives a measure of the effect of a given causal exposure based on the frequency of its occurrence in the population as a whole and its effect in increasing the relative risk to an individual.

Results

In total, 34 case-control studies met the inclusion criteria, providing stressful life events data for 1405 patients with functional neurological disorder and 2277 controls, which included healthy participants as well as individuals with neurological disease and psychiatric disorder (table 1; figure 1). In 24 studies, data were presented for patients with non-epileptic seizures, five\textsuperscript{37,39,41,54,59} reported on general or mixed functional neurological disorder, three\textsuperscript{42,44,49} provided data on functional motor disorders, and two\textsuperscript{14,46} reported on functional voice disorder (also known as functional dysphonia).

31 studies\textsuperscript{28,32,37,44–48,50,54,57,58,60} included adult participants (mean age 37·1 years [SD 6·7], range 18–77 years), whereas the remaining three studies\textsuperscript{43,51,57} came from a paediatric setting (13·7 years [0–9], 9–18 years). Both the cases and controls were mostly female participants (79·7% cases vs 72·2% controls). In 25 of the 34 studies\textsuperscript{27,29,30,32,34,36–40,42,43,47,50–53,56–58,60,61} the patients were recruited from a neurology setting, eight\textsuperscript{28,33,35,41,43,49,50,54} were from a psychiatry setting, and one study\textsuperscript{44} came from a mixed setting. 18 studies\textsuperscript{28,32,40,43,50,51,59} compared the functional patient group with a neurological disease control group, mainly with epilepsy; seven studies\textsuperscript{32,33,41,53,54,56,59} compared with healthy controls, and two studies\textsuperscript{42,48} with other psychiatric disorders control groups. In the remaining seven studies\textsuperscript{31,37,40,49,58,59,61} data were presented that derived from a comparison with two control groups concurrently (mostly including a healthy and a neurological control group).

14 studies\textsuperscript{30–35,39–41,45,46,48,49,58} reported whether stressors had taken place at any moment in life. Two studies\textsuperscript{48,60} specifically reported on stressors in adulthood, and 11 studies\textsuperscript{28,32,40,43,50,51,59} reported on those stressors having occurred during childhood. Seven studies\textsuperscript{37,40,43,54,56,59,61} presented separate rates for stressors that occurred during childhood and for those that occurred during lifetime or adulthood. Nine studies\textsuperscript{31,33,37–40,49,55,57} specified the temporal associations of life events with symptom onset.

All of the studies assessed stressors retrospectively. Study setting was either a neurology clinic, psychiatry clinic, or other. 20 studies\textsuperscript{27–29,32,33,35,41,47,48,50,52,57,60} recruited a consecutive sample. In 27 studies\textsuperscript{27–29,32,33,35,41,47,48,50,52,57,60} the diagnosis was made by a specialist. 14 adult sample studies\textsuperscript{28,32,40,44,48,50,54,57,61} reported symptom duration (excluding studies using symptom duration as an inclusion or exclusion criterion; mean 77·1 months [SD 58·2]). Of those, eight studies compared symptom duration between cases and controls (three\textsuperscript{42,44,49} of them showing a significant difference), but none tried to match controls on the basis of symptom duration.

In nine studies\textsuperscript{27,30,34,41,54,49,49,57} the interviewer (for outcome) was masked to the diagnosis. The Life Events and Difficulties Schedule (LEDS)\textsuperscript{30} is often regarded as the gold standard for such assessments in this field because it comprises of a detailed interview designed to detect a wide range of stressful life events.
array of events, but these are then rated blind and contextualised to participants’ life and circumstances to measure potential impact. Only three studies, used the LEDS interview. Most studies used standardised, structured questionnaires or standardised interviews, to assess stressors. Four studies, used investigator-designed interviews, one investigated an investigator-designed questionnaire, and two used case record data. Two studies, did not report how stressors were assessed.

The overall quality varied considerably among studies, ranging from 2–8 (with a possible maximum score of 11) on our modified Newcastle–Ottawa scale (appendix). The median score was 5 (IQR 4–6).

With regards to the association of reported stressors and the occurrence of functional neurological disorder, in the meta-analysis, we assessed the data (both continuous and dichotomous) in the form of ORs according to type of stressor and other study characteristics (figure 2). Heterogeneity was high for nearly all analyses, so random-effect analyses are presented throughout and data for sensitivity analyses are presented together (figure 2, table 2). When available, we have given summary statistics for the dichotomous data (table 2). In summary, we found higher rates of reported stressors, both recent and from childhood, in patients with functional neurological disorder compared with controls (figure 2, table 2). The risk was higher for childhood-onset symptoms than in adult life (figure 2, table 2). The OR was higher for emotional neglect (49% for cases vs 20% for controls; OR 5.6, 95% CI 2.4–13.1) than for either physical abuse (30% vs 12%; 3.9, 2.2–7.2) or sexual abuse (24% vs 10%; 3.5, 2.2–4.8; figure 2, table 2).

Calculation of the proportion of cases of functional neurological disorder that had not experienced stressors was less straightforward. Most studies only reported the rates of individual stressors found, but obviously if it is reported that, say, 34% of subjects were sexually abused, one cannot impute that 66% suffered from no other form of stressor. Only 13 studies, presenting dichotomous data reported that they had systematically ascertained that the participants had not had either severe life events, assessed by the LEDS, or any subtype of maltreatment (table 3, figure 3). However, it was clear that the rigour underpinning the assessment of no stressor, or what was meant by no stressor, was variable and we divided these 13 studies according to the method used (figure 3). Three studies used the LEDS: one examined patients with functional motor disorder, with 16% reporting no severe events, and two examined patients with functional dysphonia, finding conflicting results of 26% and 77% reporting no severe life events (figure 3). Five studies, examined a wide range of stressors but used a clinical interview rather than a structured inquiry about the experience of stressors (no stressful life events or maltreatment were reported as 14%, 15%, 25%, 51%, and 68%; figure 3). Two studies, looked at all forms of maltreatment, including sexual abuse, physical abuse, and emotional neglect, but not stressful life events, reporting no exposure as 56% and 70%, and three studies, reported data only for those participants who had not been physically or sexually abused, with rates of 0%, 56%, and 68% (figure 3).

When we calculated the PAF, we found that physical abuse had a greater effect on the cause and development of functional neurological disorder (table 2). The PAF for physical abuse was 16–9% if it occurred in childhood and 14–6% in adulthood, assuming a causal association, which was higher than for sexual abuse (8–7% in childhood and 4–8% in adulthood), and to a lesser extent emotional neglect (15–1% in childhood and 11–0% in adulthood), because physical abuse is more prevalent in the population in general (table 2).

For the sensitivity analysis, we hypothesised that various methodological issues related to the nature of the symptom, population recruited, choice of control group, the assessed time period, and the quality of the studies could affect the reported differences in frequency of stressors. We assumed that patients referred to psychiatry would have higher rates of stressors than those patients referred to neurology. In fact, the difference was much less than expected (figure 2).

The most important factor for the interpretation of results, of those we examined, was the choice of comparator group. Results differed when the comparator groups were healthy controls (OR 8.6) compared with any form of disease control (figure 2). Surprisingly,
however, the disease comparator choice had little effect and the strength of association was similar irrespective of whether the comparator was neurological (2.5) or psychiatric controls (2.0; figure 2).

When we assessed studies with a high-quality rating compared with those studies with a low rating, we found no difference for study quality (figure 2).

Regarding the method used, we compared data from only those studies that used the well validated LEDS interview (OR 4.3, 95% CI 1.4–13.2; figure 4). Not surprisingly, this outcome showed that the LEDS led to more reports of stressors than other less rigorous methods, such as questionnaires (figure 4).

When assessing whether the association differed between children and adults, we found that the strength of the association in children for stressors was much stronger than in adults (figure 2). However, numbers of participants in the paediatric studies were low (figure 2).

Studies that examined the occurrence of stressful life events that occurred immediately preceding symptom onset found an increased risk when comparing cases with controls (OR 2.8, 95% CI 1.4–6.0), but when we...
looked at studies examining the occurrence of life events throughout adult life the results were equivocal (figure 4). The broad confidence intervals might reflect the high frequency of stressful life events as a normal occurrence in adult life.

Analysis of the time period in which stressful life events occurred (without specification of the association with symptom onset) did not affect the results, with studies assessing events of recent time periods (≤3 months before assessment) showing a similar strength of association to those studies assessing events over a longer time period of 12 months before assessment (figure 4). However, we would caution that there was considerable heterogeneity within studies assessing life events over 12 months (figure 4) and one of the highest quality studies that looked at multiple timepoints leading up to symptom onset found an increasing rate of severe events with increasing proximity to symptom onset.

Regarding publication bias, we produced funnel plots that we visually inspected for all our analyses (appendix). Overall, publication bias was not evident and Egger’s bias statistics were non-significant for all summary statistics.

**Discussion**

We found that the frequency of childhood and adult stressful life events and maltreatment were increased in patients with functional neurological disorder compared with controls. The strength of the association was higher when the comparison was with healthy controls (OR 8.6) compared with neurological (2.5) or psychiatric (2.0) control groups. A variable, but in some studies substantial, proportion of patients were found to have not reported an identifiable stressor.

ORs can be difficult to interpret because they refer to the probability of two events being associated as opposed to the actual increased risk of that event. As an approximate guide for the reader, most ORs quoted in our study (ie, between 2 and 4) would be seen as a small-medium effect. The OR seen in relation to emotional neglect, or the effect of stressors on presentations of functional neurological disorder in children, would be regarded as large effects.

Emotional neglect had a stronger association with the development of functional neurological disorder, whether the neglect occurred in childhood or adult life, than the more traditionally described physical or sexual abuse. Higher-quality studies tended to find a slightly stronger association, but the quality of study and setting did not have the effect we might have expected.

However, emotional neglect had a stronger association with the development of functional neurological disorder, whether the neglect occurred in childhood or adult life, than the more traditionally described physical or sexual abuse. Higher-quality studies tended to find a slightly stronger association, but the quality of study and setting did not have the effect we might have expected.

Regarding publication bias, we produced funnel plots that we visually inspected for all our analyses (appendix). Overall, publication bias was not evident and Egger’s bias statistics were non-significant for all summary statistics.

Articles

For childhood stressors, retrospective assessment. For childhood stressors, patients report no such stressors, and our experience suggests excessive zeal in searching out maltreatment can be considered as a potential factor in the cause and development of functional neurological disorder and, when present, a potential treatment target. However, a proportion of patients do not report any such stressors, and such exposures are common in the general population; therefore, although potentially relevant to the cause, these exposures cannot be regarded as necessary to reach a diagnosis. Furthermore, clinicians should not assume the patient is consciously or unconsciously not reporting stressors if none are forthcoming after thorough questioning. Similar to most clinicians practicing in this specialty, we have had the experience of patients denying exposure to maltreatment only to disclose it later on, but perhaps less memorable are the patients who go through treatment, often recovering, and in whom no such history is ever disclosed. Our results suggest that a proportion of patients report no such stressors, and our experience suggests excessive zeal in searching out maltreatment can be just as harmful as a complete lack of interest. Of note, emotional neglect is associated with a higher individual

Figure 4: Summary of meta-analysis of adult stressful life events in conversion (functional neurological) disorder including sensitivity analysis by nature and duration of life event period assessed.

In case of multiple data from one individual study, a hierarchy was used to avoid duplication in the summary statistic: stressful life events (data from more recent timepoints first), childhood stressful life events, sexual abuse, physical abuse, emotional neglect, neurological control group, psychiatric control group, and healthy control group. *25% is low heterogeneity, 50% is moderate, and 75% is high.

problems with recall bias which can lead to either over-reporting or under-reporting have been well documented, but, for stressors occurring in adulthood, some retrospective methods have been validated with independent verification of remembered events—eg, up to 5 years with the LEDS (panel). We do not claim that our study is definitive on the topic of stressors and functional neurological disorder; the evidence has limitations. However, it should be noted that to our knowledge, our study incorporates the full extent of the case-control evidence linking stressors to functional neurological disorder. The extent, and the limitations, of the evidence for such a well engrained theory might come as a surprise to many clinicians.

The clinical and research implications from our findings are important. For the clinician faced with an individual patient, stressful life events and maltreatment should still be considered as a potential factor in the cause and development of functional neurological disorder and, when present, a potential treatment target. However, a proportion of patients do not report any such stressors, and such exposures are common in the general population; therefore, although potentially relevant to the cause, these exposures cannot be regarded as necessary to reach a diagnosis. Furthermore, clinicians should not assume the patient is consciously or unconsciously not reporting stressors if none are forthcoming after thorough questioning. Similar to most clinicians practicing in this specialty, we have had the experience of patients denying exposure to maltreatment only to disclose it later on, but perhaps less memorable are the patients who go through treatment, often recovering, and in whom no such history is ever disclosed. Our results suggest that a proportion of patients report no such stressors, and our experience suggests excessive zeal in searching out maltreatment can be just as harmful as a complete lack of interest. Of note, emotional neglect is associated with a higher individual

risk than physical or sexual abuse. Finally, our results clearly indicate that more detailed assessment of stressors results in a higher disclosure rate; it is not a task that should be rushed. Given the absence of diagnostic weight attached to these variables, this part of the assessment might often be better left to future appointments but will vary depending on circumstances.  

This systematic review supports the decision to remove the need for a recent stressor from the diagnostic criteria for functional neurological disorder in DSM-5 and suggests that ICD-11 would benefit from following this approach. The diagnosis should be made on the basis of the history plus inconsistent and incongruent neurological signs. However, the review confirms the importance of stressors as risk factors for cause. The implications are that neurologists and psychiatrists (as well as psychologists and psychotherapists) will continue to be essential for this specialty. In terms of ICD-11, it is therefore imperative that the condition is coded in both F and G codes—although we long for the day when we drop this dualistic approach and bring ICD into the 21st century with a unitary code for clinical brain sciences disorders. Work on the association between stressful life events and maltreatment and illness behaviour, as well as altered brain functioning in patients with functional neurological disorder, will move our understanding forward regarding potential mechanisms.

In summary, this review has aggregated data from 34 studies with 1405 patients and is consistent in the findings that exposure to stressful life events and maltreatment in childhood and adult life is associated with an increase in the risk of functional neurological disorder, but not all patients with functional neurological disorder have identifiable stressors.

Contributors
TN, SA, ASD, RAK, KR, AC, and JS had the idea for the study. LL, AC, and JS contributed to the study conception and design. LL and JS did the systematic literature research and selected studies for inclusion. JAP, TN, and KR contributed additional literature researches. LL extracted data and JAP checked all data for accuracy. LL and JAP assessed the quality of the studies, AC resolved any disagreements. LL and JS did statistical analyses and JS made the figures. LL wrote the first draft of the manuscript and JS and AC did the redrafts. ST critically reviewed the analyses and the manuscript. All authors critically revised the manuscript for important intellectual content, and contributed and approved the final draft.

Declaration of interests
AC is a paid editor for the Journal of Neurology, Neurosurgery, and Psychiatry and is paid for independent testimony in court on a range of related topics. JS created and maintains the Functional and Dissociative Neurological Symptoms self-help site (http://www.neurosymptoms.org) for patients and is paid for independent testimony in court, including testimony relating to functional disorders. All other authors declare no competing interests.

Acknowledgments
LL is supported by a DAAD scholarship (German Academic Exchange Service). JS is supported by an NHS Scotland Career Research Fellowship. TN and ASN are supported by the National Institute for Health Research (NIHR) Biomedical Research Centre at the South London and Maudsley National Health Services (NHS) Foundation Trust and the Institute of Psychiatry, Psychology and Neuroscience.

Panel: Issues with methods for studies of stressful life events and maltreatment in patients with functional neurological disorder

Case finding and recruitment
- Diagnostic suspicion bias: some patients might have been given the diagnosis because they had experienced stressors, when other patients without stressors might have just been left as “blackouts?cause”.
- Misdiagnosis: suggested to be rare by published studies.
- Recruitment bias: those patients seen in psychiatric clinics might have had more stressors and might present with psychiatric comorbidity.
- DSM definition: patients with functional neurological disorder as defined strictly by DSM-IV or earlier would by definition have to have a “conflict” or “other stressors”. In fact, few studies appeared to adhere to DSM.
- Diagnosis: diagnosing functional neurological disorder might alter patients’ reviews of their life history and cause an erroneous reassessment of humdrum events as substantial stressors.

Sample sizes
Small sample sizes are unlikely to find a significant result even if the effect is present (type II error).

Blinding
Only nine studies measured outcome masked to the diagnosis.

Confounding with comorbidities
Possibly the case for depression and anxiety. Could also be true for personality disorder and other variables only partially dependent on functional neurological disorder.

Interviewer factors
A patient might not trust the interviewer or feel ready to disclose events to them. It is argued that stressors will only be disclosed following prolonged clinical engagement and build up of trust. However, against this argument it should be noted that our results found that those studies which assessed reported stressors solely on the basis of clinical contact had the lowest rates of detection and those which used a very comprehensive structured measure, such as the Life Events and Difficulties Schedule (LEDS), had the highest. What was less clear was the nature of the clinical contact and whether that included patients who had had prolonged psychotherapy.

Multiple different measures of stressors
Difficulties of stressful life event studies in general
- Recall bias can occur in both directions: patients might overly recall negative versus positive events, other patients might have experienced terrible maltreatment but deny it in interviews and questionnaires.
- Contextualising events: stressful life events take on meaning because of the context in which they occur. Only contextualised methods, such as the LEDS, assess events in this way. Even when they do it is very hard to mask them in studies.
- Timeframe: some studies were not specific regarding the timeframe of stressors and appear to have included also those stressors after symptom onset.
- Symptom-specific events: eg. conflict over speaking out in dysphonia study might be prevalent but hidden in general questionnaires assessing stressors.

Exposure not usually corroborated with external records

Heterogeneity
If high then considerable caution is warranted when interpreting results of meta-analysis.

Publication bias
Negative studies not published.
